Keywords: transmembrane domain, talin, integrin, polyphenol, epidermal growth factor receptor (EGFR)

ABSTRACT

Epigallocatechin gallate (EGCG) is the principal bioactive ingredient in green tea and has been reported to have many health benefits. EGCG influences multiple signal transduction pathways related to human diseases, including redox, inflammation, cell cycle, and cell adhesion pathways. However, the molecular mechanisms of these varying effects are unclear, limiting further development and utilization of EGCG as a pharmaceutical compound. Here, we examined the effect of EGCG on two representative transmembrane signaling receptors, integrin αIIbβ3 and epidermal **growth factor receptor (EGFR). We report that EGCG inhibits talin-**induced integrin αIIbβ3 **activation, but** it activates αIIbβ3 in the absence **of talin both in a purified system and in cells. This apparent paradox was explained by the** fact that the activation state of αIIbβ3 is tightly regulated by the topology of β3 transmembrane **domain (TMD); increases or decreases in TMD embedding can activate integrins. Talin** increases the embedding of integrin β3 TMD **resulting in integrin activation, whereas we observed here that EGCG decreases it, thus opposing talin-induced integrin activation. In the absence of talin, EGCG decreases the TMD embedding which can also disrupt the integrin** α-β TMD interaction, leading to integrin **activation. EGCG exhibited similar paradoxical behavior in EGFR signaling. EGCG alters the topology of EGFR TMD and activates the receptor in the absence of EGF, but inhibits EGF-induced EGFR activation. Thus, this widely ingested polyphenol exhibits pleiotropic effects on transmembrane signaling by modifying the topology of TMDs.**

Green tea is one of the most popular drinks for thousands of years, both as a beverage and as a herbal medicine. Indeed, green tea has many clinically reported health benefits, including the prevention of cardiovascular diseases (1,2) and cancer (3). Studies on the beneficial effects of green tea using cellular or animal models have recently converged on EGCG, the most abundant

polyphenol considered as health promoting phytonutrient in green tea, and have found EGCG to influence multiple signal transduction pathways related to antioxidation, inflammation, cell cycle, and cell adhesion (4). However, the molecular mechanism underlying those effects has remained elusive. Although EGCG has been suggested to have a number of molecular targets (5), only DNA methyltransferase (6) and 67 kDa laminin receptor (7) have been demonstrated to directly respond to EGCG in an *in vitro* system. On the other hand, recent nuclear magnetic resonance spectroscopy studies clearly showed that EGCG can interact with model lipid membranes (8,9), which implies that biological membrane can be a molecular target of EGCG. Furthermore, the EGCG-lipid interaction can cause a deformation of the lipid bilayer, e.g. by inducing an expansion of the lipid bilayer (10) and/or altering the thickness of the membrane (11). Since membrane-receptor interactions are important in maintaining the proper TMD topology, structures, and hence function of the transmembrane receptors (12,13), chemical and physical alteration in biological membrane may cause changes in activities of those proteins (14). However, whether such lipid-EGCG interaction contributes to and how it could account for the broad effects of EGCG on many cell signaling pathways are yet to be elucidated.

We hypothesized that EGCG exerts its effect on transmembrane receptor signaling by interacting with a lipid bilayer and thereby changing the TMD topology and signaling of a broad spectrum of transmembrane proteins. We tested this hypothesis using integrin αIIbβ3 and EGFR, two prototypical signaling receptors. Integrin αIIbβ3 is a heterodimeric transmembrane adhesion receptor that has a low affinity for its ligands in the resting state ("inactive") and a high affinity in the stimulated state ("active" or "activated"). The affinity of integrin αIIbβ3 is regulated by TMD interaction of its α and β subunits (15) which depends on the precise tilt angle of the β3 TMD determined by the lipid-protein interaction (16,17). Indeed, the physiological integrin-activating protein, talin (18), activates the integrin by altering the tilt angle of integrin β3 TMD (19,20). The other model transmembrane receptor, EGFR, normally exists in an inactive monomeric state and is activated upon ligand-induced homodimerization, in which the topology of its TMD may play a role (21,22)**.** Here, we investigate the effect of EGCG on these two prototypical transmembrane signaling receptors and propose that EGCG can alter the membrane embedding of their TMDs, which in turn modulates transmembrane signaling by these receptors.

RESULTS AND DISCUSSION

Pleiotropic effect of EGCG on activation of integrin αIIbβ3 – Although EGCG is reported to have anti-thrombotic effects (23), addition of EGCG to platelets, the main cellular mediators of arterial thrombosis, causes complex responses. For example, EGCG inhibited aggregation of thrombin-stimulated platelets, but, paradoxically, caused aggregation of unstimulated platelets at the same dose (24). To better understand the physiological role of this widely consumed polyphenol, we first tested the effect of EGCG on activation of recombinant integrin αIIbβ3 in Chinese hamster ovary (CHO) cells where the integrin is normally in low affinity state; with addition of increasing concentration of EGCG, there was a progressive increase in activation as measured by binding of PAC1, a ligand-mimetic, activation specific integrin αIIbβ3 antibody (25) (Fig. 1A, empty bars). The EGCG-induced increase in PAC1 binding was reduced by washing out EGCG (Supplemental Fig. 1), showing the effect is reversible and does not require the known oxidation-dependent reactivity toward primary amines (26). Physiological activation of this integrin requires binding of talin to the cytoplasmic domain of the β3 subunit (27). To ask whether EGCG induces physiological activation, we utilized a mutant αIIbβ3(Y747A) that does not bind talin (28). This mutant showed similar activation by EGCG (Fig. 1A, filled bars). Thus, EGCG-induced integrin activation is not dependent on the known intracellular signaling pathway.

To directly test the effects of EGCG on talin-induced integrin activation, we introduced talin head domain (THD), the integrin activating talin fragment (18), into CHO cells expressing integrin αIIbβ3 (CHO/αIIbβ3), and examined the effects of EGCG on the talin-induced activation. EGCG blocked THD-induced αIIbβ3 activation in a dose-

dependent manner, whereas EGCG alone induced integrin activation (Fig. 1B).

Because of complexity of cellular components that might mediate these paradoxical effects of EGCG, we utilized an *in vitro* reconstitution system in which purified integrin αIIbβ3 was embedded in nanodiscs, islands of 10 nm lipid bilayer encircled by membrane scaffold protein (29). In the reconstituted system, addition of purified THD can activate the integrin (30). The integrin nanodiscs were first captured to the surface of assay plate coated with anti-integrin β3 extracellular antibody (AP3), and the degree of integrin activation was measured by PAC1 binding to the immobilized integrin nanodiscs (Fig. 1C). EGCG activated the integrin nanodiscs in a dose-dependent manner (Fig. 1C, green line), as it did in cells. Addition of purified THD increases PAC1 binding in the system as previously shown (30) and the THD-induced increase was inhibited by addition of increasing amount of EGCG (Fig. 1C, blue line), showing a similar paradoxical effects of EGCG in the purified system as in cells (Fig. 1B).

To examine the effect of EGCG on activated integrins in cells, we utilized αIIbβ3(D723R) mutant which is activated in a talin-dependent manner in CHO cells (28). The D723R mutation disrupts the electrostatic interaction between αIIb(R995) and β3(D723), weakening the integrin αIIb-β3 TMD interaction and thus favoring the activated state (31). The activating effect of the D723R mutant is dependent upon integrin-talin interactions, as its activation is abolished by disrupting integrin binding to endogenous talin, e.g. by the β3(Y747A) mutation (28). When we added EGCG to the cells expressing αIIbβ3(D723R), in sharp contrast to the activating effect observed with the wild type integrin, we observed that EGCG induced an initial suppression of activation which peaked at 200 μM EGCG (Fig. 2A). At higher concentration, however, EGCG induced activation exhibiting a distinct biphasic effect (Fig. 2A). Next, we tested another activating mutant, αIIbβ3(L712R), in which TMD is predicted to shorten from 29 to 19 amino-acids due to the polar residue in the middle of TMD (32). The activating effect of the αIIbβ3(L712R) mutant is talin-independent, as its activation is not affected by the loss of the talin-integrin interactions (28,33). In contrast to αIIbβ3(D723R), EGCG had no significant effect on the L712R mutant (Fig. 2B,C).

Opposing changes of integrin β3 TMD *topology by EGCG and talin* – To find an explanation for these paradoxical effects, we noted the insensitivity of αIIbβ3(L712R) mutant to EGCG. This mutant activates integrin by shortening the β3 TMD (32), whereas talin does it by increasing the lipid embedding of the β3 TMD (19), both of which changes can alter the β3 TMD tilt angle thereby disrupting the αIIb-β3 TMD interaction leading to integrin activation (17). In addition, several studies demonstrated that EGCG can interact with phospholipids and even can decrease the thickness of a lipid bilayer (9-11), which may alter the lipid embedding of TMDs. To test this idea, we investigated whether EGCG can change the embedding of integrin TMD by adapting a β3 TMD embedding assay (19). As EGCG had considerable spectral overlap with bimane, the fluorophore used in the previous study, we used another environment-sensitive fluorophore, mero60, whose fluorescence increases in a more hydrophobic environment and does not overlap with that of EGCG (34). We conjugated the dye to either the N-terminal end (β3(L694C)) or C-terminal end (β3(I721C)) of β3 TMD and reconstituted the β3 TMD-cytoplasmic tail peptides into phospholipid nanodiscs (Fig. 3A). EGCG decreased the fluorescence of mero60 at either N-terminal end or C-terminal end of β3 TMD (Fig. 3B-C), indicating that EGCG causes both the N and C-terminal ends of β3 TMD to become less embedded. The decrease in fluorescence is a specific result from altered membrane embedding of β3 TMD, as the EGCG-induced reduction in fluorescence disappeared after addition of 2% SDS to disassemble the nanodisc (not shown). These data strongly suggest that EGCG reduces the embedding of the β3 TMD, although other mechanisms, e.g. EGCG-induced local unraveling of the helix, cannot be ruled out. Because the optimal association of integrin αIIb and β3 TMD depends on the precise topology of β3 TMD (17), our data suggest that EGCG alters the β3 TMD topology thereby destabilizing the α-β TMD association and inducing integrin activation.

Consistent with our previous report (19) that THD increases the embedding of the β3 TMD domain, THD increased the fluorescence

intensities of mero60 conjugated to β3(L694C) or β3(I721C) (Fig. 3D-E, black dotted lines). The increased fluorescence reflects an altered topology of the β3 TMD (19), which can also disrupt the association of integrin α and β TMDs. Intriguingly, EGCG reversed the THD-induced increase in the fluorescence of mero60 in both β3(L694C) and β3(I721C) nanodiscs (Fig. 3D-E, green dotted lines), indicating that EGCG alters the topology of the β3 TMD in a manner that opposes the effect of THD (Fig. 3F). We propose that EGCG-induced change of β3 TMD topology opposes that induced by talin. Thus, it can offset the talin-induced changes in TMD topology and integrin activation. The embedding assay using integrin β3 TMD appears more sensitive to EGCG than integrin activation assay. In the embedding assay, concentrations of EGCG from 25 μM to 100 μM caused large fluorescence changes both in the absence (Fig. 3B-C) or presence of talin (Fig. 3D-E); whereas, higher concentrations of EGCG were required to affect the integrin activation assay (Fig. 1C). This may be due to the additional stabilizing effect of the presence of the extracellular domains, which are absent in the β3 TMD embedding assays, on integrin αβ association and activation.

Effects of EGCG on transmembrane signaling though a receptor tyrosine kinase – If the ECGG-induced topological change of integrin β3 TMD is due to an EGCG-lipid interaction, we reasoned EGCG should also have effects on other transmembrane proteins with signaling functions. To test this hypothesis, we focused on the receptor tyrosine kinases (RTKs) because the dimerization of their TMDs in the lipid bilayer may play a role in activation of those receptors (21,22). Indeed, EGCG was reported to inhibit activation of RTKs such as EGFR (35,36) possibly due to effects on lipid order (36). Pretreatment of HEK293 cells stably expressing EGFR with EGCG inhibited EGF-induced EGFR phosphorylation (Fig. 4A). In contrast, EGCG treatment in the absence of EGF induced EGFR phosphorylation in a concentration-dependent manner (Fig. 4B). Furthermore, EGCG decreased the fluorescence intensity of mero60 attached to C-terminal region of the nanodisc-embedded EGFR TMD (Fig. 4C). These data suggest that a topological change of EGFR TMD induced by EGF (37) can be reversed by the action of EGCG, and that EGCG-induced topological change in the absence of EGF may favor dimerization of EGFR TMDs leading to activation.

Our results show that EGCG can change the TMD topologies of receptors and activate those receptors. Conversely, when physiological activation involves shifts in TMD topology, then EGCG can oppose those shifts, and inhibit transmembrane signaling. We propose that such a dual effect can account for the conflicting reported effects of EGCG. Recent studies showed that EGCG can bind to lipid bilayers and reside near the phosphate head groups of phospholipids, and that the interaction is further stabilized by cation-π interaction between one of the ring structures in EGCG and quaternary amine of the phospholipid head group (8). Because the interactions between TMDs and phospholipids can influence the topology of TMDs in a lipid bilayer by mechanisms such as snorkeling of the basic lysine side chain into the phosphate head groups of the phospholipids (16), EGCG may alter the interaction of the TMD with the phosphate head group thus leading to changes in TMD topology. Alternatively, the rigidity of lipids induced by insertion of EGCG into hydrophobic lipid bilayer as suggested by molecular simulation study (38), or the rigidity of lipid-inserted EGCG itself due to its less flexible aromatic rings, might alter the tilt angle of TMDs causing less embedding. Future studies will be required to address these hypotheses; however, our observation that EGCG has a dual effect on transmembrane signaling by modulating lipid embedding of TMDs provides an attractive mechanism to explain some of EGCG's pleiotropic effects on transmembrane signaling.

EXPERIMENTAL PROCEDURES

Reagents, cell lines, and plasmids – 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) and 1,2-dimyristoyl-sn-glycero-3-phospho-(1'-rac-glycerol) (DMPG) were purchased from Avanti Polar Lipids, Inc. Membrane scaffold protein (MSP1D1) was kindly provided by Dr. Steven Sligar (University of Illinois at Urbana-Champaign). PAC1 and D57 were described previously (16). Anti-FLAG antibody (M2) and Anti-phosphotyrosine antibody (4G10) were purchased from Sigma-Aldrich and Merck Millipore, respectively. CHO/αIIb and

CHO/αIIbβ3 cells were generated by infecting CHO cells with lentivirus encoding αIIb and/or β3 as previously described (16). HEK/EGFR cells were kindly provided by Dr. Seung-Taek Lee (Yonsei University). The β3 TMD-tail fused with N-terminal 6xHis and ketosteroid isomerase (KSI) in the pET-31 expression vector was described previously (19). Similarly, the EGFR TMD (Pro637 ~ Gln701) construct containing N-terminal 6xHis and KSI with cysteine mutation at Phe667 was generated by ligation of the PCR-amplified EGFR TMD region into the pET-31 expression vector.

Flow cytometry – Transfection and flow cytometry were performed with a similar procedure as described before (23). Briefly, CHO or CHO/αIIb cells were transfected with various integrin constructs using Lipofectamine LTX and Plus reagents (Life Technologies) or Lipofectamine 2000 (Life Technologies). CHO/αIIbβ3 cells were transfected with total of 10 μg plasmids which include 1 μg tdTomato cDNA as a transfection marker. At 24 h after transfection, cells were detached by trypsinization and treated with EGCG for 10 min. Those cells were stained with PAC1 followed by allophycocyanin-conjugated anti–mouse IgM antibody. When integrin constructs were transfected, cells were co-stained with D57 to gate cells with similar high αIIbβ3 expression.

EGFR phosphorylation assay – Serum-starved subconfluent HEK/EGFR cells were treated with varying concentration of EGCG for 30 min before EGF treatment (final 50 ng/ml). Cells were lysed by a lysis buffer (20 mM HEPES, pH 7.4, 150 mM NaCl, 1% Triton X-100, 10 mM EDTA, pH 7.4, supplemented with PhosStop (Roche) and protease inhibitor cocktail (Roche)). After clarification by centrifugation at 17,000 g for 30 min, the clarified lysates were incubated at 4°C overnight in the presence of 3 μg anti-FLAG antibody and the bound proteins were precipitated with protein G sepharose. The bound proteins were analyzed by SDS-PAGE and subsequent western blot with anti-phosphotyrosine antibody and anti-EGFR antibody.

Expression and purification of TMD peptides – The preparation of integrin nanodiscs was performed essentially as previously described (19). Briefly, 6xHis-KSI fused TMD proteins were expressed in E.coli BL21(DE3) and purified using HiTrap Chelating HP column charged with Ni2+. The Asp-Pro bond between KSI and TMD peptide in the purified TMD proteins was cleaved in 10% formic acid for 120 mins at 80 °C (24). The resulting TMD peptide was then dialyzed against a buffer containing 50 mM Tris-HCl, pH 7.4, 500 mM NaCl, and 6 M urea, and then passed through a Ni2+-NTA column again to absorb the KSI, leaving the purified TMD peptide in the solution. The TMD peptide was labeled with excess mero60 (1:5 molar ratio). 0.1 % Triton X-100 was added to the labeled TMD peptide and the labeled TMD peptide was then dialyzed extensively against 0.1 % Triton X-100 in Tris-buffered saline (TBS, 20 mM Tris-HCl, pH 7.4, 150 mM NaCl).

Preparation of integrin nanodiscs – The preparation of integrin nanodiscs was previously described (25). Briefly, DMPC and DMPG lipids were dissolved in chloroform or chloroform/methanol mixture, mixed into 1:1 ratio, and dried onto a glass tube with steady flow of argon. The lipid mixture was dissolved in 100 mM cholate in TBS. To assemble nanodiscs, 360 μl of the 1:1 lipid mixture (50 mM), 1 ml of 200 μM MSP1D1, and the purified TMD peptides (10 μM) or the purified integrin αIIbβ3 from human platelets (10 μM) were mixed. The mixture was added with two volumes of Biobeads SM-2 (Bio-Rad) to initiate nanodisc assembly and incubated overnight at room temperature in the dark. The assembled nanodiscs were further purified with a size exclusion column (hi-load 16/60 Superdex 200) with TBS as the column buffer. When necessary, the nanodiscs were concentrated using Ultracel-30k (Millipore).

Fluorescence spectroscopy – 200 μl of the purified nanodiscs were mixed with 50 μl of various concentrations or EGCG (and THD in the case of β3 TMD nanodiscs). After 30 min of incubation at room temperature, the emission spectrum (from 605 nm to 655 nm) at the excitation wavelength, 593 nm, was scanned with 1 nm interval using FluoroMax-2 Spectrofluorometer (Instruments S.A., Inc.). The fluorescence from unlabeled TMD peptide, talin, empty nanodiscs, or buffer was negligible. The fluorescence of the samples was re-measured after addition of 2% SDS (final concentration).

Acknowledgments: We thank Mr. Se-Jong Kim, Mr. Si Hoon Park, and Dr. Hyun Kyu Song (Korea University) for their technical supports and helpful discussion.

Conflict of interest: The authors declare that they have no conflicts of interest with the contents of this article. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Author Contributions: F.Y., M.H.G., and C.K. designed the research. F.Y., C.Y., and J.K. performed experiments. C.J.M. and K.M.H. synthesized the fluorescence dye. F.Y., C.Y., D.P., M.H.G., and C.K. analyzed the data. F.Y., C.Y., and C.K. wrote the manuscript, which was edited by M.H.G.

FIGURE LEGENDS

FIGURE 1. EGCG both activates and inhibits activation of integrin αIIbβ3 in cells and a **reconstituted system.**
(A) CHO cells stably expressing integrin αIIb were transfected with wild type or talin binding-deficient mutant (Y747A) integrin β3. EGCG-treated cells with comparable αIIbβ3 expression (high D57 staining) were gated and the degree of integrin activation of these gated cells was measured by PAC1, an activation specific integrin αIIbβ3 antibody. Specific PAC1 binding was calculated as MFI-MFI_0, where MFI is the mean fluorescence intensity of bound PAC1 and MFI_0 is that in the presence of 10 mM EDTA or 20 μM eptifibatide both of which inhibit integrin αIIbβ3-ligand binding. (B) CHO cells stably expressing αIIbβ3 were transfected with empty vector or talin head domain (THD) together with tdTomato cDNA as a transfection marker. Specific PAC1 binding of tdTomato positive cells treated with different concentration of EGCG was calculated and shown as described in (A). (C) The configuration of the integrin nanodisc activation assay is shown. Integrin nanodiscs were captured on to an ELISA plate coated with anti-β3 antibody (AP3). Specific PAC1 binding was calculated as L-L_0, where L is PAC1 binding to the captured integrin nanodisc measured by chemiluminescence and L_0 is that in the presence of eptifibatide. The effects of EGCG on specific PAC1 binding were measured in the absence (green line) or presence of purified THD (10 μM) (blue line). Throughout the panels, error bars represent standard errors (n=3), and ANOVA multiple comparison using the Bonferroni's test was performed to test for significant differences between EGCG-treated and non-treated samples. **P<0.01, ***P<0.001, ****P<0.0001.

FIGURE 2. EGCG has distinct effects on talin-dependent and talin-independent αIIbβ3 activation.
(A-B) CHO cells were transfected with integrin αIIb and activating β3 mutants, β3(D727R) (talin-dependent) or β3(L712R) (talin-independent), and specific PAC1 binding was measured as described in Fig. 1A. (C) % inhibition of integrin activation was calculated as 100 x (P_0-P)/P_0, where P_0 is the specific PAC1 binding in the absence of EGCG and P is that in the presence of EGCG. Note that EGCG initially inhibits and then increases activation of the talin-dependent αIIbβ3(D723R) mutant whereas it does not inhibit the talin-independent αIIbβ3(L712R) mutant. Error bars represent standard errors (n=3). ****P<0.0001.

FIGURE 3. EGCG alters β3 TMD topological changes in the opposite direction to talin. (A) The environment-sensitive dye, mero60, was conjugated to β3 TMD-tail peptide through the cysteine mutation at Leu694 residue to probe the embedding change of β3 TMD at the outer membrane leaflet or at Ile721 residue at the inner membrane leaflet. The mero60-labeled β3 TMD peptides were then incorporated into phospholipid nanodiscs. (B) EGCG decreases the fluorescence intensity of L694C-mero60 nanodiscs. EGCG is not fluorescent at the wavelength range measured in the analysis. Fluorescence intensities were normalized to the maximum fluorescence intensity in the mero60-β3-TMD nanodiscs without EGCG. (C) The fluorescence of I721C-mero60 nanodiscs were analyzed as in (B). (D) Mero60-β3(L694C) nanodiscs were incubated with 10 μM THD with or without EGCG. EGCG reverses the increase of mero60 fluorescence intensity induced by THD. (E) The effect of EGCG on mero60-β3(I721C) nanodiscs were analyzed as in (D). (F) Proposed model of EGCG's action. Because the association of integrin αIIb and β3 TMD depends on the precise tilt angle of β3 TMD, either increased or decreased embedding of the β3 TMD can disrupt the α-β TMD association and activate the integrin. Talin binding to integrin β3 tail

increases the TMD tilt angle, thereby activating integrin. EGCG interacts with the phospholipid bilayer and reduces the integrin TMD tilting angle. When both effects are present, EGCG first neutralizes the effect of talin but continued reduction in the tilt angle by EGCG activates the integrin.

FIGURE 4. EGCG has a dual effect on EGFR signaling. (A) HEK293 cells expressing FLAG-tagged human EGFR (HEK/EGFR) were serum-starved overnight and pretreated with different concentration of EGCG. 30 min after EGCG treatment, cells were stimulated with 50 ng/ml EGF for additional 30 min. EGFR was immunoprecipitated and analyzed with anti-phosphotyrosine antibody and anti-EGFR antibody. The degree of phosphotyrosine signal per precipitated EGFR band intensities were normalized to un-stimulated control (0%) and EGF-treated control (100%), and shown as bar graph for each sample. Error bars represent standard errors (n=3). Representative western blots are shown below. (B) Phosphorylation of unstimulated EGFR in the presence of different concentration of EGCG was analyzed as in (A). EGCG induced EGFR phosphorylation in a dose-dependent manner. Error bars represent standard errors (n=3). For panels A and B, one way ANOVA multiple comparison using the Bonferroni's test was performed to test for significant differences between EGCG-treated and non-treated samples. *P<0.05, ****P<0.0001. (C) Effects of EGCG on lipid embedding of EGFR TMD. Left, Purified EGFR TMD peptide (EGFR(F667C)) labeled with mero60 was reconstituted into nanodiscs, and the effect of EGCG on the embedding of EGFR TMD was analyzed as in Fig. 3B. Right, EGCG has little effect on mero60 fluorescence when EGFR TMD nanodiscs were solubilized with 2% SDS.

SUPPLEMENTAL FIGURE 1. EGCG reversibly induces integrin activation in CHO/αIIbβ3 cells. CHO cells stably expressing αIIbβ3 were incubated for 30 min in the absence or presence of 200 μM EGCG. Those cells were washed twice with Dulbecco Modified Eagle Medium for 10 min per each washing, and then treated with PAC1 in the absence or presence of 200 μM EGCG again as indicated. PAC1 binding to these cells were analyzed and shown as histogram.
